Probabilistic Inference for Predictive Maintenance in Resource-Constrained Industrial Systems

Sub-Saharan African Context

CSC5341 — Inferential Statistics

Full Project Report

Author: Ali Lamididi

Supervisor: Dr. Amine Amar

March 2026

Executive Summary

This report presents a complete probabilistic inference pipeline for predictive maintenance of industrial machinery, developed across five milestones of the CSC5341 Inferential Statistics course. The project is deeply contextualized within the industrial reliability challenges of Sub-Saharan Africa (SSA), where unplanned machine downtime imposes severe financial costs on small and medium enterprises operating under constrained infrastructure—with downtime costs averaging $38,500 per hour in South Africa alone.

The problem is formulated as Bayesian inference over latent machine health states—Healthy, Degrading, and Critical—using a Hidden Markov Model (HMM) driven by multivariate sensor observations (temperature, vibration, pressure). This probabilistic framing enables uncertainty-aware decision-making in environments characterized by noisy sensors, intermittent connectivity, and limited data.

Milestone I establishes the project foundation: problem identification grounded in SSA industrial research, paradigm justification comparing frequentist and Bayesian approaches, full HMM model specification with plate notation, and a synthetic Data-Generating Process (DGP) calibrated against a real-world Kaggle dataset.

Milestone II implements an exact inference engine using the Forward–Backward algorithm, delivering per-time-step posterior marginals and a Viterbi-based MAP baseline. The algorithm runs in $O(T \cdot K^2)$ and achieves < 0.03 seconds on $T = 200$, $K = 3$, correctly recovering ground-truth latent states with $> 95\%$ accuracy.

Milestone III addresses computational intractability at scale by transitioning to approximate inference via a Vectorized Even-Odd Block Gibbs Sampler. Convergence is validated with Gelman-Rubin $\hat{R} < 1.05$ and $D_{\mathrm{KL}} \approx 0.00018$ bits against exact posteriors.

Milestone IV performs rigorous inference diagnostics (posterior entropy analysis, $\hat{R}$, ESS), implements the Baum-Welch EM algorithm as a full model-based learning procedure using the Forward–Backward engine as its E-step, and conducts BIC-based model selection across $K \in \{2, 3, 4\}$ states. The EM algorithm converges to parameter estimates within $< 5\%$ relative error of ground truth.

Milestone V synthesizes all milestones through an information-theoretic lens, proposes a novel Neural-Symbolic Amortized HMM extension for non-stationary SSA maintenance, and presents a publication-quality research proposal targeting the real-time inference gap in low-resource industrial environments.

1 Introduction

Industrial machinery operates through continuous phases of physical wear and degradation. In manufacturing environments across Sub-Saharan Africa, where spare-part supply chains are volatile and skilled maintenance labor is scarce, unplanned machine failures represent existential financial risks. Research by ABB (2023/24 Industrial Outlook) indicates that 72% of South African industrial operators experience unplanned stoppages at least once per month, with average downtime costs of approximately $38,500 per hour. A single 8-hour outage can therefore erase the annual profit margin of a small-to-medium enterprise.

Predictive maintenance—the practice of inferring machine health from sensor data in order to schedule interventions before failures occur—offers a principled solution. However, most predictive maintenance systems are designed for high-resource environments with clean, continuous, high-frequency data. Deploying such systems in SSA contexts is complicated by power disruptions, low-bandwidth connectivity, sensor degradation, and scarcity of historical failure records.

This project addresses these challenges by formulating predictive maintenance as a *probabilistic inference problem* over latent machine health states. The Hidden Markov Model (HMM) framework is chosen because it explicitly encodes temporal dynamics of machine degradation, handles noisy and incomplete observations, and produces uncertainty-aware posterior distributions rather than deterministic point predictions.

The report proceeds through five milestones:

- **Milestone I:** Problem identification, paradigm justification, model specification, and synthetic data generation.
- **Milestone II:** Exact inference—Forward–Backward algorithm, posterior marginals, MAP sequence via Viterbi, and frequentist contrast.
- **Milestone III:** Approximate inference—intractability analysis, Vectorized Even-Odd Gibbs Sampling, convergence diagnostics, and scaling experiments.
- **Milestone IV:** Model evaluation—inference diagnostics, Baum-Welch EM parameter learning, and BIC-based model selection.
- **Milestone V:** Critical synthesis, information-theoretic analysis, limitations, research proposal, and decision support system.

2 Milestone I: Project Foundation and Analytical Approach

2.1 Component 1: Problem Identification

This project addresses the problem of predictive maintenance for industrial machines, formulated as a probabilistic inference task over hidden system states. Using the Machine Predictive Maintenance Classification dataset, the objective is to infer the underlying health condition of a machine from multivariate sensor data (temperature, torque, rotational speed, and tool wear).

This problem is non-trivial and suitable for probabilistic modeling because:

- The true machine condition is not directly observable (latent)
- Sensor measurements are noisy and partially informative
- Machine degradation evolves over time, introducing hidden state dynamics
- Decisions must be made under uncertainty, not certainty

Thus, instead of treating this as a simple classification problem, it is formulated as an inference problem over latent variables representing machine health states. This formulation is particularly relevant in real-world industrial settings where observability is inherently limited, and where maintenance decisions must balance risk, cost, and uncertainty rather than relying on deterministic predictions.

2.1.1 The SSA Industrial "Reliability Gap"

In Sub-Saharan Africa (SSA), industrial resilience is significantly constrained by a structural "maintenance paradox": while industrial machines are often older and more failure-prone, the cost of spare parts and skilled labor is elevated due to import dependency and supply chain volatility.

Financial Impact of Unplanned Downtime. In South Africa, the most industrialized economy in the region, unplanned downtime remains a primary driver of productivity loss. Research by ABB (2023/24 Industrial Outlook) indicates that 72% of industrial operators experience unplanned stoppages at least once per month. The average cost of downtime is R724,000 ($\approx$ \$38,500 USD) per hour. A single 8-hour outage can result in losses of approximately \$308,000—sufficient to erode the annual profit margin of a small-to-medium enterprise (SME) in a single event.

Maintenance Maturity. According to the Southern African Maintenance Association (SAMA), approximately 18–20% of firms continue to rely on Run-to-Failure (RTF) maintenance strategies, largely driven by the high cost of retrofitting legacy assets with high-fidelity IoT sensor systems.

2.1.2 The Data Scarcity Constraint (Global South Context)

Industrial settings in SSA are characterized by substantial physical and digital constraints:

Infrastructure Instability. Frequent power disruptions introduce artifacts into sensor measurements, resulting in intermittent signal loss and non-stationary noise patterns. World Bank enterprise

surveys estimate that firms in SSA lose approximately 6–10% of annual sales due to power outages.

Connectivity Limitations. Many industrial sites depend on low-bandwidth cellular connectivity, limiting continuous data streaming and constraining cloud-native ML deployments.

Sensor Degradation. Harsh environmental conditions lead to sensor drift, making readings unreliable indicators of the true machine state over time.

At the same time, predictive maintenance systems have been shown to reduce downtime by 35–45%, reduce maintenance costs by 25–30%, and decrease breakdowns by up to 70–75%. These benefits are not fully realized in SSA due to the constraints above, making probabilistic approaches—which explicitly handle uncertainty, noise, and incomplete information—particularly relevant.

2.1.3 Why Probabilistic Modeling is the Optimal Intervention

Given these constraints, deterministic machine learning approaches (e.g., standard Random Forests or Neural Networks) are inherently fragile: they produce point estimates without associated uncertainty measures and fail under out-of-distribution conditions caused by sensor noise, missing data, or infrastructure instability.

By framing the problem as a latent variable inference task, the proposed approach estimates the posterior distribution:

$$P(Z_t \mid X_{1:T}) \tag{1}$$

The posterior over a specific state k:

$$P(Z_t = k \mid X_{1:T}) \tag{2}$$

provides a confidence measure for each possible machine state, enabling risk-adjusted decision-making. Maintenance intervention can be triggered only when:

$$P(Z_t = \text{Critical}) > \tau \tag{3}$$

where τ is a decision threshold calibrated based on the relative cost of machine failure versus preventive maintenance.

2.1.4 Comparative Analysis

Feature	**Deterministic ML**	**Probabilistic Inference (Proposed)**
Data Quality Requirement	High (clean, dense datasets)	Moderate (robust to noise and missing data)
Output Interpretation	Binary (e.g., Healthy/Failed)	Probabilistic (confidence distribution over states)
Computational Requirements	High (especially during training)	Efficient (leverages priors, reduces data dependence)
Applicability in SSA Context	Low (sensitive to instability and noise)	High (robust under uncertainty and infrastructure constraints)

2.1.5 Inferential Question

> *Given observed sensor data from industrial machines, how can we infer the hidden health state of a machine, quantify the uncertainty of this inference, and use it to guide maintenance decisions?*

This involves three components. First, **latent state estimation**: the latent variable is $Z_t \in \{\text{Healthy}, \text{Degrading}, \text{Critical}\}$, and the goal is to estimate $P(Z_t \mid X_{1:T})$. Second, **uncertainty quantification** through the posterior $P(Z_t = k \mid X_{1:T})$, which provides a probabilistic confidence measure for each state. Third, **decision support**: whether to continue monitoring, schedule preventive maintenance, or trigger immediate intervention.

2.2 Component 2: Paradigm Justification and Model Specification

2.2.1 Frequentist Approach

In a frequentist framework, the predictive maintenance problem is formulated as parameter estimation and classification. Parameters θ are estimated via Maximum Likelihood Estimation (MLE):

$$\hat{\theta} = \arg\max_{\theta} P(X \mid \theta) \tag{4}$$

Machine states are then predicted using these point estimates:

$$\hat{Z}_t = \arg\max_{z} P(Z_t = z \mid X_t, \hat{\theta}) \tag{5}$$

2.2.2 Bayesian Approach

In the Bayesian framework, both latent states Z and parameters θ are treated as random variables. Prior beliefs about parameters are encoded through $P(\theta)$, and observed data is incorporated via the

likelihood $P(X \mid Z, \theta)$. The solution is the full posterior:

$$P(Z, \theta \mid X) = \frac{P(X \mid Z, \theta)\, P(Z \mid \theta)\, P(\theta)}{P(X)} \tag{6}$$

Inference focuses on computing the marginal posterior:

$$P(Z_t \mid X_{1:T}) \tag{7}$$

2.2.3 Justification of the Bayesian Paradigm

The Bayesian approach is selected because: (i) the machine health state is latent and not directly observable; (ii) sensor data in SSA contexts is often noisy, sparse, and unreliable, making explicit uncertainty modeling essential; (iii) maintenance decisions under resource constraints require full posterior distributions rather than point estimates; and (iv) Bayesian methods naturally support sequential and adaptive inference over time.

From a decision-theoretic standpoint, the Bayesian posterior is the minimal sufficient statistic for optimal decision-making under uncertainty. Specifically, the expected cost of a maintenance decision d given posterior $P(Z_t \mid X_{1:T})$ is:

$$\mathbb{E}[C(d)] = \sum_k P(Z_t = k \mid X_{1:T}) \cdot C(d, k) \tag{8}$$

where $C(d, k)$ is the cost of decision d when the true state is k. This formulation is not accessible to frequentist point estimators.

2.2.4 Hidden Markov Model Specification

The system is modeled as a Hidden Markov Model (HMM) with two types of random variables:

- **Latent variables** Z_t: machine health state at time t
- **Observed variables** X_t: sensor measurements at time t

Initial state:

$$Z_1 \sim P(Z_1) \tag{9}$$

State transitions (Markov property):

$$Z_t \mid Z_{t-1} \sim P(Z_t \mid Z_{t-1}) \tag{10}$$

Emissions (observations):

$$X_t \mid Z_t \sim P(X_t \mid Z_t) \tag{11}$$

Graphical structure:

$$Z_1 \to Z_2 \to Z_3 \to \cdots \to Z_T, \qquad Z_t \to X_t \quad \forall\, t$$

The full joint generative model factorizes as:

$$P(Z_{1:T},\, X_{1:T},\, \theta) = P(\theta)\; P(Z_1) \prod_{t=2}^{T} P(Z_t \mid Z_{t-1}) \prod_{t=1}^{T} P(X_t \mid Z_t,\, \theta) \tag{12}$$

2.2.5 Model Components

Latent variables: $Z_t \in \{\text{Healthy}, \text{Degrading}, \text{Critical}\}$, $t = 1, \ldots, T$.

Observed variables: $X_t = (x_t^{(1)}, x_t^{(2)}, x_t^{(3)})$ — temperature, vibration, pressure.

Parameters:

$$\pi_k = P(Z_1 = k) \quad \text{(initial state distribution)} \tag{13}$$

$$A_{ij} = P(Z_t = j \mid Z_{t-1} = i) \quad \text{(transition matrix)} \tag{14}$$

$$\theta_k = \{\mu_k, \Sigma_k\} \quad \text{(emission parameters per state)} \tag{15}$$

Emission model:

$$X_t \mid Z_t = k \;\sim\; \mathcal{N}(\mu_k,\, \Sigma_k) \tag{16}$$

Prior distributions (Bayesian formulation):

$$\pi \sim \text{Dirichlet}(\alpha), \qquad A_i \sim \text{Dirichlet}(\beta) \quad \forall\, i \tag{17}$$

$$\mu_k \sim \mathcal{N}(\mu_0,\, \Lambda_0), \qquad \Sigma_k \sim \text{Inverse-Wishart}(\Psi,\, \nu) \tag{18}$$

The Dirichlet priors are conjugate to the categorical likelihood, which simplifies posterior computation in the Baum-Welch E-step. The Normal-Inverse-Wishart prior over (μ_k, Σ_k) is the conjugate prior for the multivariate Gaussian emission, enabling closed-form M-step updates. The hyperparameters are set to be weakly informative: $\alpha = \beta = (1, 1, 1)$ (uniform Dirichlet), $\mu_0 = \mathbf{0}$, $\Lambda_0 = 10 \cdot \mathbf{I}$, $\Psi = \mathbf{I}$, $\nu = D + 2$.

2.3 Component 3: Data Collection and Methodology

2.3.1 Data Source

The primary data source is the Kaggle dataset "Machine Predictive Maintenance Classification", which contains multivariate sensor measurements from industrial machines, including air temperature,

process temperature, rotational speed, torque, and tool wear, along with labeled failure events.

2.3.2 Synthetic Data Generation (DGP)

Because the original dataset does not include explicit temporal sequences or ground-truth latent health states required for HMM inference, a synthetic Data-Generating Process (DGP) is implemented:

- Feature distributions from the Kaggle dataset are used to estimate realistic emission parameters (μ_k, Σ_k).
- Latent states evolve via predefined transition matrix A with a realistic degradation structure.
- Synthetic sequences $(Z_{1:T}, X_{1:T})$ are generated by sampling latent trajectories and observations conditionally.

DGP parameters:

$$\pi = [0.8,\ 0.15,\ 0.05] \quad \text{(likely start healthy)} \tag{19}$$

$$A = \begin{pmatrix} 0.9 & 0.09 & 0.01 \\ 0.05 & 0.85 & 0.10 \\ 0.02 & 0.08 & 0.90 \end{pmatrix} \tag{20}$$

Emission means (μ_k) and covariances (Σ_k) are calibrated from the Kaggle dataset's sensor statistics per machine type.

2.3.3 Ethical Implications and Potential Biases

Data Bias. The Kaggle dataset may not represent the full diversity of SSA industrial conditions, leading to distributional mismatch. The DGP may generate overly idealized data.

Model Assumption Bias. The discrete state space oversimplifies continuous degradation. The Markov assumption ignores long-term dependencies. Gaussian emissions may fail to capture outliers typical of SSA power-surge events.

Prior Bias. Poorly chosen priors may bias the posterior in low-data settings. All priors are designed to be weakly informative.

Decision Impact. Incorrect inference may lead to delayed maintenance (underestimating Critical probability) or unnecessary interventions (overestimating it). Mitigation strategies include robustness checks across noise levels and sensitivity analysis of the decision threshold τ.

Fairness Consideration. Deploying a model trained on Western industrial data in SSA contexts without local validation risks systematic underperformance in target environments—a form of algorithmic unfairness. Proactive mitigation requires collecting in-situ calibration data from SSA partners.

3 Milestone II: Algorithmic Blueprint and Exact Inference

3.1 C1: Inference Task Formalization

Let $Z_{1:T} = (Z_1, \ldots, Z_T)$ denote the latent health states and $X_{1:T} = (X_1, \ldots, X_T)$ the observed sensor vectors. The inference engine must answer the following queries.

3.1.1 Posterior Marginals

The primary target is the per-time-step posterior:

$$p(Z_t \mid X_{1:T}), \quad t = 1, \ldots, T \tag{21}$$

These posterior marginals quantify uncertainty over machine health at each time step given all observations, enabling risk-aware decisions—for example, triggering an inspection when $p(Z_t = \text{Critical} \mid X_{1:T})$ exceeds a threshold.

3.1.2 MAP Sequence

The secondary target is the Maximum A Posteriori (MAP) latent trajectory:

$$\hat{Z}_{1:T} = \arg\max_{Z_{1:T}} p(Z_{1:T} \mid X_{1:T}) \tag{22}$$

3.1.3 Marginal Likelihood (Evidence)

The marginal likelihood:

$$p(X_{1:T}) = \sum_{Z_{1:T}} p(X_{1:T},\, Z_{1:T}) \tag{23}$$

serves as a normalization constant and as a model selection criterion.

3.1.4 Naive Computational Complexity

Naive inference enumerates all possible latent trajectories. With K states across T time steps, the number of trajectories is K^T, and naive computation is exponential:

$$O(T \cdot K^T) \tag{24}$$

For $K = 3$ states and $T = 200$ time steps, this amounts to $3^{200} \approx 10^{95}$ trajectories—computationally intractable. This motivates dynamic programming algorithms that exploit the HMM chain structure.

3.2 C2: Exact Algorithm — Forward–Backward

3.2.1 Algorithm Choice and Correctness

We implement the Forward–Backward algorithm, which is exact for HMMs. The HMM is a chain-structured graphical model:

$$Z_1 \to Z_2 \to \cdots \to Z_T, \qquad X_t \perp X_{s\neq t} \mid Z_t$$

This conditional independence structure allows global inference to be decomposed into local recursions. Forward–Backward uses dynamic programming to avoid summing over K^T trajectories by reusing intermediate forward and backward messages.

Complexity:

$$O(T \cdot K^2) \tag{25}$$

For $K = 3$ and $T = 200$, this is only $200 \times 9 = 1800$ operations.

3.2.2 Implementation

(i) Emission probabilities. Compute the likelihood for each time step and state:

$$p(X_t \mid Z_t = i) = \frac{1}{(2\pi)^{D/2}|\Sigma_i|^{1/2}} \exp\Big(-\tfrac{1}{2}(X_t - \mu_i)^\top \Sigma_i^{-1}(X_t - \mu_i)\Big)$$

(ii) Forward recursion. Define forward messages $\alpha_t(i) = p(X_{1:t}, Z_t = i)$.

Initialization:

$$\alpha_1(i) = \pi_i \, p(X_1 \mid Z_1 = i)$$

Recursion ($t \geq 2$):

$$\alpha_t(j) = p(X_t \mid Z_t = j) \sum_{i=1}^{K} \alpha_{t-1}(i) \, A_{ij} \tag{26}$$

(iii) Backward recursion. Define backward messages $\beta_t(i) = p(X_{t+1:T} \mid Z_t = i)$.

Initialization: $\beta_T(i) = 1$

Recursion ($t \leq T - 1$):

$$\beta_t(i) = \sum_{j=1}^{K} A_{ij} \, p(X_{t+1} \mid Z_{t+1} = j) \, \beta_{t+1}(j) \tag{27}$$

(iv) Posterior computation.

$$p(Z_t = i \mid X_{1:T}) = \frac{\alpha_t(i) \, \beta_t(i)}{\sum_{k=1}^{K} \alpha_t(k) \, \beta_t(k)} \tag{28}$$

Numerical stability. Forward messages are normalized at each time step using scaling constants to prevent underflow over long sequences.

3.2.3 Results

Exact Inference Results (K

```
Posterior marginals (first 5 time steps):
  t=1: [1.000, 0.000, 0.000]   → Confident: Healthy
  t=2: [1.000, 0.000, 0.000]   → Confident: Healthy
  t=3: [0.000, 1.000, 0.000]   → Confident: Degrading
  t=4: [0.954, 0.046, 0.000]   → Mostly Healthy (some ambiguity)
  t=5: [0.000, 1.000, 0.000]   → Confident: Degrading

MAP states (first 20): [0 0 1 0 1 1 1 0 0 0 0 0 0 0 0 2 2 2 2 2]
Forward-Backward runtime: 0.029955 seconds
Log-likelihood: -1284.37
Accuracy vs. ground truth: 95.0%
```

The inferred MAP sequence closely matches the true latent trajectory, confirming correctness of the implementation. Non-zero probabilities for alternative states at ambiguous time steps (e.g., $t = 4$: $[0.954, 0.046, 0]$) demonstrate the model's ability to capture residual uncertainty rather than making overconfident decisions.

3.3 C3: Baseline and Frequentist Contrast — Viterbi

3.3.1 Frequentist Baseline

We implement the Viterbi algorithm as a deterministic baseline:

$$\hat{Z}_{1:T} = \arg\max_{Z_{1:T}} p(X_{1:T}, Z_{1:T}) \tag{29}$$

Viterbi can be interpreted as a MAP sequence estimate. It does not produce posterior uncertainty over states at each time step.

3.3.2 Comparison: Bayesian vs. Frequentist

Aspect	**Bayesian (Forward–Backward)**	**Frequentist (Viterbi)**
Output	Probabilities $p(Z_t \mid X_{1:T})$	Single sequence $\hat{Z}_{1:T}$
Uncertainty	Yes (explicit posterior)	No (deterministic)
Decision support	Risk-based / thresholdable	Potentially overconfident
Accuracy on $T = 200$	95.0%	95.0%
Computational cost	$O(TK^2)$	$O(TK^2)$

3.3.3 Credible vs. Confidence Intervals

Credible (Bayesian). The posterior marginal $p(Z_t = k \mid X_{1:T})$ is a direct probability statement about the machine being in state k at time t given the observed data. A 95% credible interval $[a, b]$ satisfies $\int_a^b p(Z_t \mid X_{1:T})\, dz = 0.95$—a direct probability statement about the parameter.

Confidence (Frequentist). A 95% confidence interval procedure covers the true parameter value in 95% of repeated datasets. It is *not* a direct probability statement about the latent state for a single realized dataset.

This distinction is critical in high-stakes settings such as predictive maintenance, where acting on a single deterministic estimate may lead to premature or delayed interventions, whereas posterior probabilities allow decisions to be calibrated based on risk thresholds.

4 Milestone III: Approximate Inference and Computational Scaling

4.1 C1: Intractability Argument and Algorithm Selection

4.1.1 Formal Intractability of Exact Inference

The Forward–Backward algorithm runs in $O(T \cdot K^2)$. For the three discrete health states used in Milestone II this is trivially fast. However, modeling fine-grained continuous degradation requires $K \gg 3$:

- At $K = 100$ micro-states: each Forward step requires $100^2 = 10{,}000$ multiplications per time step.
- At $K = 1000$: 10^6 multiplications per step, and memory for 1000×1000 transition matrices becomes prohibitive.
- In the continuous limit, the sum transitions to a non-conjugate integral:

$$\alpha_t(z_t) = p(x_t \mid z_t) \int \alpha_{t-1}(z_{t-1})\, p(z_t \mid z_{t-1})\, dz_{t-1} \tag{30}$$

Lacking a closed-form conjugate solution for generic non-linear industrial emissions, exact inference becomes formally intractable.

Quantified complexity growth: Scaling experiments with $T = 2000$ and $K \in \{3, 10, 20, 35, 60\}$ confirm that exact inference wall-clock time grows as $O(K^2)$, with the algorithm exceeding practical time limits beyond $K > 35$.

4.1.2 Algorithm Selection: MCMC vs. Variational Inference (VI)

Variational Inference (Mean-Field). Standard Mean-Field VI assumes total factorization across the sequence:

$$q(Z) = \prod_{t=1}^{T} q(Z_t) \tag{31}$$

The factorization assumption severs sequential Markov chain dependencies. In predictive maintenance, recognizing that Z_{t+1} is heavily conditional on Z_t is fundamental. Imposing factorization yields overconfident variance approximations and destroys chronological history, rendering standard VI unsuitable for HMMs.

MCMC (Gibbs Sampling). MCMC dynamically tracks an ergodic Markov chain over the state configuration. Gibbs Sampling iteratively conditions local states against their Markov Blanket:

$$p(Z_t \mid Z_{-t},\, X_{1:T}) \propto p(Z_t \mid Z_{t-1})\, p(Z_{t+1} \mid Z_t)\, p(X_t \mid Z_t) \tag{32}$$

Because MCMC targets the exact posterior asymptotically, it strictly preserves chronological depen-

dencies without forcing artificial independence. Update complexity reduces to $O(K)$ linear processing per step.

Final Selection: Gibbs MCMC is selected for its mathematical guarantee of preserving structural covariance while achieving tractable $O(K)$ per-step scaling.

4.2 C2: Approximate Algorithm Implementation

4.2.1 Vectorized Even-Odd Block Gibbs Sampling

Standard element-wise Gibbs algorithms update Z_t consecutively, incurring Python interpreter overhead. We implement an **Advanced Vectorized Checkerboard (Even-Odd) Block Gibbs Sampler**.

Theoretical insight. From the conditional structure, any even-indexed state Z_{2k} depends exclusively on its adjacent odd neighbors Z_{2k-1} and Z_{2k+1}. Therefore, all even states are conditionally independent of each other given the odd states:

$$P(Z_{\text{even}} \mid Z_{\text{odd}},\, X) = \prod_k P(Z_{2k} \mid Z_{2k-1},\, Z_{2k+1},\, X_{2k}) \tag{33}$$

This enables computing transitions for half the timeline simultaneously using NumPy C-backed log-sum-exp operations, eliminating the sequential Python loop.

Algorithm:

Algorithm 1 Vectorized Even-Odd Block Gibbs Sampler

```
Initialize Z^(0) randomly; initialize M chains
for n = 1, ..., N_sweeps do
    Even block: Compute log p(Z_t^(n) | Z_{t-1}^(n-1), Z_{t+1}^(n-1), X_t) for all even t simultaneously via vectorized log-sum-exp
    Sample all even Z_t^(n) in parallel
    Odd block: Repeat for all odd t, conditioning on updated even states
    Collect sample Z^(n)
end for
return chains after burn-in
```

4.2.2 Convergence Monitoring

Gelman-Rubin statistic ($\hat{R}$):

$$\hat{V} = \frac{N-1}{N}\,W + \frac{1}{N}\,B, \qquad \hat{R} = \sqrt{\frac{\hat{V}}{W}} \tag{34}$$

where B is between-chain variance and W is within-chain variance. $\hat{R} \approx 1$ indicates convergence. Target: $\hat{R} < 1.05$.

Effective Sample Size (ESS):

$$\text{ESS} = \frac{N_{\text{valid}}}{1 + 2\sum_{\tau=1}^{\infty} \rho_\tau} \tag{35}$$

Implementation: $M = 4$ independent chains, $N = 500$ sweeps, burn-in $= 100$.

4.3 C3: Algorithmic Analysis and Comparison

4.3.1 KL Divergence: Exact vs. Approximate

$$D_{\text{KL}}(P_{\text{exact}} \,\|\, Q_{\text{appx}}) = \sum_{t,k} \gamma_{\text{exact}}^{(t,k)} \log\left(\frac{\gamma_{\text{exact}}^{(t,k)}}{\gamma_{\text{appx}}^{(t,k)}}\right) \approx 0.00018 \text{ bits} \tag{36}$$

This negligible KL divergence confirms that removing exact combinatorial mechanisms retains essentially identical posterior marginals.

4.3.2 Scaling Results

Scaling Experiment: T

K	Exact (seconds)	Gibbs (seconds)
3	0.04	0.31
10	0.41	0.34
20	1.67	0.38
35	5.12	0.43
60	15.23	0.51

Exact inference crosses the practical threshold at $K > 35$; Gibbs maintains near-linear growth.

4.3.3 Pareto Efficiency Analysis

A Pareto trace mapping D_{KL} against wall-clock time across varied sweep counts N reveals:

- $N < 100$ **sweeps:** Rapid D_{KL} inflation due to initialization bias; chains have not escaped their starting configurations.
- $N \approx 250$**:** Optimal convergence point—posterior fidelity plateaus ($D_{\text{KL}} < 0.001$) while computation remains tractable.
- $N > 1000$**:** Negligible accuracy gains; computational waste. The mixing autocorrelation saturation barrier is identified here.

Primary error sources: (1) Initialization bias (burn-in < 100): corrected by discarding early samples. (2) Mixing lag (autocorrelation ρ_τ at small τ): reduced by the block updating strategy, which decorrelates adjacent states faster than scalar updates.

4.3.4 Conclusion: Milestone III

The Vectorized Even-Odd Block Gibbs Sampler successfully transitions the inference pipeline from $O(K^2)$ exact computation to $O(K)$ approximate inference, achieving negligible information loss ($D_{\mathrm{KL}} = 0.00018$ bits) while enabling scaling to $K \gg 35$ states that would be computationally intractable under the exact Forward–Backward framework.

5 Milestone IV: Model Evaluation, Criticism, and Learning

5.1 C1: Inference Diagnostics

Rigorous diagnostics are performed across both inference engines to assess reliability, convergence, and calibration.

5.1.1 Posterior Entropy Analysis

The Shannon entropy of the posterior marginal at each time step quantifies how much uncertainty remains after observing all sensor data:

$$H(Z_t \mid X_{1:T}) = -\sum_{k=1}^{K} p(Z_t = k \mid X_{1:T}) \log p(Z_t = k \mid X_{1:T}) \tag{37}$$

Interpretation. High entropy at a time step indicates that the model is uncertain about the machine's health state—typically occurring at state transition boundaries or under high sensor noise. Low entropy indicates confident inference. The maximum possible entropy for $K = 3$ states is $\log(3) \approx 1.099$ nats (uniform posterior).

Posterior Entropy Diagnostics (K

```
Max possible entropy (K=3 states): 1.0986 nats
Mean posterior entropy:            0.1823 nats  (16.6% of max)
Fraction of steps with entropy > 0.5 (uncertain): 12.5%
```

Interpretation. The mean posterior entropy of 0.1823 nats represents 16.6% of the maximum possible entropy. This indicates that, on average, the inference engine maintains high confidence about the machine's health state given the observed sensor data. The 12.5% of time steps with $H > 0.5$ nats corresponds to boundary transitions between health states—exactly the time steps where diagnostic uncertainty is highest and where additional caution is warranted.

Information-theoretic significance. The difference between prior entropy $H(Z_t) = \log(K)$ and posterior entropy $H(Z_t \mid X_{1:T})$ is the mutual information $I(Z_t; X_{1:T})$—a direct measure of how much information the sensor observations carry about the latent machine health state. The large entropy reduction (from 1.099 to 0.182 nats) quantifies the diagnostic value of the sensor system.

5.1.2 MCMC Diagnostics: Gelman-Rubin $\hat{R}$

$\hat{R}$ is computed across all time steps, sampled at every 10th step (20 diagnostic points):

Gelman-Rubin Diagnostics (M

```
Mean R-hat across time steps:     1.0021
Max  R-hat across time steps:     1.0187
Fraction with R-hat < 1.05:      100.0%
```

Interpretation. All $\hat{R}$ values fall below the convergence threshold of 1.05, confirming that all four chains have converged to the same stationary distribution. The mean $\hat{R} = 1.0021$ is extremely close to 1.0, indicating near-perfect chain mixing. The maximum $\hat{R} = 1.0187$ (occurring at a state transition boundary) remains well within acceptable limits.

5.1.3 MCMC Diagnostics: Effective Sample Size (ESS)

ESS quantifies the equivalent number of independent samples in the MCMC chain, accounting for autocorrelation:

$$\text{ESS} = \frac{N_{\text{valid}}}{1 + 2\sum_{\tau=1}^{\infty} \hat{\rho}_\tau} \tag{38}$$

For the Vectorized Even-Odd Block Gibbs implementation with $N = 500$ sweeps and burn-in $= 100$, the effective number of post-burn samples is 400. Across all time steps, the mean ESS is approximately $320/400 = 80\%$ efficiency—indicating effective mixing with low autocorrelation. This high ESS ratio confirms that the block updating strategy successfully reduces within-chain autocorrelation.

5.1.4 Autocorrelation Analysis

Trace plots for representative time steps show rapid mixing with autocorrelation function (ACF) values dropping below 0.1 by lag $\tau = 5$ for most time steps. This rapid decorrelation is a direct consequence of the Even-Odd block strategy: by simultaneously updating half the states conditioned on the other half, the sampler takes larger effective steps through the posterior geometry than scalar Gibbs would allow.

5.1.5 Variational Diagnostic: ELBO Tightness

Although the primary approximate inference engine is MCMC (selected over VI in Milestone III), we assess the tightness of the Mean-Field ELBO bound as a diagnostic comparison. The ELBO is:

$$\mathcal{L}(q) = \mathbb{E}_{q(Z)}[\log p(X, Z)] - \mathbb{E}_{q(Z)}[\log q(Z)] = \log p(X) - D_{\text{KL}}(q(Z) \| p(Z \mid X)) \tag{39}$$

The gap $\log p(X) - \mathcal{L}(q) = D_{\text{KL}}(q \| p)$ measures how much information the variational approximation loses relative to the true posterior. For the HMM, the Mean-Field factorization severs temporal

dependencies, leading to a substantially positive KL gap—confirming that MCMC was the correct algorithmic choice for this model.

5.1.6 Reliability Assessment

Based on the diagnostics above, the inference engine has produced reliable, well-converged results:

- **Technical convergence** (all $\hat{R} < 1.05$, high ESS): confirmed.
- **Practical reliability**: the $D_{\mathrm{KL}} = 0.00018$ bits between exact and MCMC posteriors confirms that approximate inference introduces negligible decision-making error.
- **Remaining uncertainty**: the 12.5% of high-entropy time steps represent genuine epistemic uncertainty at state transition boundaries—not an artifact of algorithmic failure. These are correctly flagged as "uncertain" periods where additional sensor data would be most informative.
- **Algorithmic tuning recommendation**: increasing the number of sensors (D) or reducing the emission noise covariance Σ_k would further reduce posterior entropy at transition points, without requiring changes to the inference algorithm.

5.2 C2: Model-Based Learning — Baum-Welch EM Algorithm

5.2.1 Learning Task Formulation

In realistic deployment, the true HMM parameters $(\pi, A, \mu_k, \Sigma_k)$ are not known and must be learned from sensor data alone. We frame this as a **maximum likelihood parameter estimation** task:

$$\hat{\theta} = \arg\max_{\theta} \log p(X_{1:T} \mid \theta) = \arg\max_{\theta} \log \sum_{Z_{1:T}} p(X_{1:T}, Z_{1:T} \mid \theta) \tag{40}$$

The summation over all latent sequences makes direct optimization of this marginal likelihood intractable. The Expectation-Maximization (EM) algorithm resolves this by iteratively optimizing a lower bound—the expected complete-data log-likelihood.

5.2.2 Baum-Welch EM: Theoretical Foundation

The Baum-Welch algorithm is an EM procedure specialized to HMMs, where the Forward–Backward algorithm serves as the E-step. This demonstrates the deep connection between inference and learning: the same algorithm that answers "what is the machine's health state?" (M2) is reused as a subroutine inside the parameter learning procedure.

E-step: Compute sufficient statistics using the Forward–Backward algorithm:

$$\gamma_t(k) = p(Z_t = k \mid X_{1:T}, \theta^{\text{old}}) \tag{41}$$

$$\xi_t(i,j) = p(Z_t = i, Z_{t+1} = j \mid X_{1:T}, \theta^{\text{old}}) \tag{42}$$

where $\xi_t(i,j)$ is the joint posterior over consecutive state pairs:

$$\xi_t(i,j) \propto \alpha_t(i)\, A_{ij}\, p(X_{t+1} \mid Z_{t+1} = j,\, \theta^{\text{old}})\, \beta_{t+1}(j) \tag{43}$$

M-step: Update parameters to maximize the expected complete-data log-likelihood $Q(\theta, \theta^{\text{old}}) = \mathbb{E}_q[\log p(X_{1:T}, Z_{1:T} \mid \theta)]$:

$$\hat{\pi}_k = \gamma_1(k) \tag{44}$$

$$\hat{A}_{ij} = \frac{\sum_{t=1}^{T-1} \xi_t(i,j)}{\sum_{t=1}^{T-1} \gamma_t(i)} \tag{45}$$

$$\hat{\mu}_k = \frac{\sum_{t=1}^{T} \gamma_t(k)\, X_t}{\sum_{t=1}^{T} \gamma_t(k)} \tag{46}$$

$$\hat{\Sigma}_k = \frac{\sum_{t=1}^{T} \gamma_t(k)\, (X_t - \hat{\mu}_k)(X_t - \hat{\mu}_k)^\top}{\sum_{t=1}^{T} \gamma_t(k)} \tag{47}$$

Convergence guarantee. Each EM iteration monotonically increases the marginal log-likelihood $\log p(X_{1:T} \mid \theta)$. This follows from the standard EM lower bound inequality:

$$\log p(X \mid \theta^{\text{new}}) \geq Q(\theta^{\text{new}}, \theta^{\text{old}}) \geq Q(\theta^{\text{old}}, \theta^{\text{old}}) = \log p(X \mid \theta^{\text{old}}) \tag{48}$$

5.2.3 Results

Baum-Welch EM Results (K

```
Convergence: iteration 23 (| log-lik| < 1e-4)
Final log-likelihood: -1291.44

Learned vs. True initial distribution:
  Learned : [0.7821, 0.1643, 0.0536]
  True    : [0.8000, 0.1500, 0.0500]
  Relative error: 2.7%

Learned vs. True transition matrix:
```

```
  Learned A:                    True A:
  [[0.898, 0.089, 0.013],      [[0.90, 0.09, 0.01],
   [0.052, 0.842, 0.106],       [0.05, 0.85, 0.10],
   [0.021, 0.083, 0.896]]       [0.02, 0.08, 0.90]]
  Max element-wise error: 0.008

Learned vs. True emission means ():
  All sensor dimensions within 3.5% of true values
```

Interpretation. The Baum-Welch algorithm successfully recovers the true HMM parameters from observations alone, without access to the ground-truth latent states $Z_{1:T}$. The small relative errors ($< 5\%$ across all parameters) demonstrate that the EM procedure, powered by the Forward–Backward inference engine, accurately identifies the structure of the underlying data-generating process. This is a direct validation of the complete Bayesian inference pipeline.

The log-likelihood convergence curve is monotonically non-decreasing, confirming correct EM implementation. The small final log-likelihood gap between the learned model (-1291.44) and the true model (-1284.37) reflects the inherent identifiability constraints of parameter estimation from finite data.

5.2.4 BIC-Based Model Selection

We compare models with $K \in \{2, 3, 4\}$ states using the Bayesian Information Criterion (BIC), which approximates the log marginal likelihood $\log p(X \mid M)$ with a complexity penalty:

$$\mathrm{BIC}(M) = -2 \log p(X \mid \hat{\theta}_M) + |\theta_M| \cdot \log T \tag{49}$$

where $|\theta_M| = K + K^2 + K \cdot D + K \cdot D(D+1)/2$ is the number of model parameters.

Interpretation. The BIC criterion correctly identifies $K = 3$ as the optimal model. The improvement in log-likelihood from $K = 2$ to $K = 3$ ($+195.77$) far outweighs the additional parameter complexity penalty ($\Delta = 15 \cdot \log(200) \approx 79.6$). The improvement from $K = 3$ to $K = 4$ ($+12.55$) is insufficient to justify the additional parameters ($\Delta = 19 \cdot \log(200) \approx 101$), correctly penalizing over-parameterization.

Connection to Bayes Factors. In a full Bayesian treatment, model selection would use the Bayes Factor:

$$\mathrm{BF}_{M_3,M_2} = \frac{p(X \mid M_3)}{p(X \mid M_2)} \tag{50}$$

BIC provides a large-sample approximation: $\log \mathrm{BF}_{M_j,M_i} \approx -\frac{1}{2}(\mathrm{BIC}_j - \mathrm{BIC}_i)$. Here, $\log \mathrm{BF}_{M_3,M_2} \approx 160.6$, providing overwhelming evidence for the three-state model.

6 Milestone V: Synthesis, Innovation, and Communication

6.1 C1: Critical Synthesis and Unifying Analysis

6.1.1 How Paradigm Choice Shaped the Entire Pipeline

Choosing the Bayesian paradigm at the outset had cascading downstream consequences at every stage of the pipeline. Table 1 summarizes how each milestone's choices were shaped by the foundational paradigm decision.

Table 1: Paradigm influence on pipeline design and interpretation

Stage	**Frequentist path (counterfactual)**	**Bayesian path (chosen)**
Model design	Logistic regression, point predictions, fixed parameters	HMM with full posterior, Dirichlet-NW priors
Exact inference	MLE / Viterbi — single best path, no uncertainty	Forward–Backward — full posterior marginals $p(Z_t \mid X_{1:T})$
Uncertainty output	Asymptotic confidence intervals (not directly interpretable for latent states)	Credible intervals (exact probability statements)
Parameter learning	Maximum likelihood EM (standard Baum-Welch without priors)	Bayesian EM with Dirichlet-NW priors, posterior regularization
Approximate scaling	Deterministic approximations (Kalman filter linearizations)	MCMC—asymptotically exact, preserves chain dependencies
Decision support	Hard thresholds on point predictions	Posterior-calibrated threshold τ on $p(Z_t = \text{Critical})$

The most consequential paradigm impact was in the approximate inference stage: the Bayesian posterior provided a principled quantity ($p(Z_t \mid X_{1:T})$) that MCMC could asymptotically target, whereas a frequentist framework would have required distributional approximations without convergence guarantees. The Bayesian framing also enabled Baum-Welch EM to incorporate Dirichlet priors over transition matrices, preventing degenerate solutions when certain transitions are rare in finite data—a critical robustness property for SSA deployments where data is scarce.

6.1.2 Information Theory as the Unifying Thread

KL divergence appeared as a central unifying quantity across three distinct roles in the pipeline:

1. Variational inference criterion. Mean-Field VI minimizes $D_{\mathrm{KL}}(q(Z) \| p(Z \mid X))$. The choice to use MCMC over VI was directly motivated by the information-theoretic argument that the Mean-Field factorization would create a large, irreducible KL gap due to severed temporal dependencies—a

gap that cannot be reduced by more VI iterations, only by adopting a more expressive variational family.

2. Algorithm evaluation. The achieved $D_{\mathrm{KL}}(\gamma_{\mathrm{exact}} \| \gamma_{\mathrm{MCMC}}) = 0.00018$ bits quantifies the information lost when using the MCMC approximation instead of the exact Forward–Backward posterior. This negligible gap confirms that the Gibbs sampler operates on the correct posterior geometry.

3. Posterior entropy as diagnostic. The posterior entropy $H(Z_t \mid X_{1:T}) = -\sum_k p(Z_t = k \mid X) \log p(Z_t = k \mid X)$ provides a diagnostic measure of residual uncertainty after observing all sensor data. The mean posterior entropy of 0.182 nats (16.6% of the maximum 1.099 nats) quantifies the diagnostic value of the sensor system. Equivalently, the mutual information:

$$I(Z_t; X_{1:T}) = H(Z_t) - H(Z_t \mid X_{1:T}) \approx 1.099 - 0.182 = 0.917 \text{ nats} \tag{51}$$

measures the expected reduction in uncertainty about machine health states achieved by the sensor system—an operational metric that can guide sensor placement decisions in SSA deployments.

4. BIC as marginal likelihood approximation. The BIC model selection criterion is an information-theoretic quantity: it approximates $-2 \log p(X \mid M)$, the negative log marginal likelihood, penalizing model complexity through a term proportional to $|\theta| \log T$. This connects model selection directly to the minimum description length (MDL) principle: the preferred model is the one that compresses the data most efficiently.

6.1.3 Limitations of the Complete Pipeline

A rigorous analysis of limitations distinguishes between **fundamental** (irreducible by design) and **addressable** (correctable with additional resources) constraints.

Fundamental limitations:

1. **Discrete state space.** Three health states is an idealization. Real machine degradation is continuous. Addressing this requires Continuous-State SSMs (Kalman filters, particle filters) or Neural HMMs with continuous latent spaces.

2. **First-order Markov assumption.** Long-range dependencies (cumulative fatigue, seasonal operating patterns, maintenance history) are not captured by the first-order Markov structure. Higher-order HMMs or attention-based sequence models would be required.

3. **Gaussian emissions.** Industrial sensor data is often heavy-tailed due to power surges, sensor faults, and thermal shocks—a regime where Gaussian tails systematically underestimate the probability of extreme observations. Student-t emissions or mixture emissions would improve robustness.

Addressable limitations:

1. **Fixed parameters.** In deployment, μ_k and Σ_k drift as sensors age and ambient conditions change. This is addressable via online EM (sequential Baum-Welch) or the Neural HMM extension proposed below.
2. **SSA calibration gap.** Parameters learned from the Kaggle dataset may not transfer to SSA sensor environments. This is addressable by collecting in-situ calibration data from SSA manufacturing partners through structured partnerships.
3. **Single-machine modeling.** The current pipeline treats each machine independently. In a factory with multiple machines, hierarchical Bayesian pooling would enable data sharing across machines, dramatically improving inference quality for recently installed or infrequently failing assets.

Implications for generalization. The pipeline is best understood as a proof-of-concept for the inference framework rather than a production-ready system. Deployment in SSA contexts would require: (1) collection of local sensor calibration data, (2) validation against real failure events, (3) integration of expert domain knowledge about local machine types and failure modes, and (4) user interface design appropriate for operators without data science backgrounds.

6.2 C2: Innovation and Research Proposal

6.2.1 Innovative Extension: Neural-Symbolic Amortized Inference

Motivation. The core limitation of the current pipeline is the assumption of stationary emission parameters (μ_k, Σ_k fixed). In SSA industrial environments, sensors drift over time due to dust accumulation, temperature stress, and aging electronics. A static HMM will progressively misclassify machine states as its emission model diverges from reality. Furthermore, the Forward–Backward algorithm requires $O(T \cdot K^2)$ computation per inference query—prohibitive for real-time embedded deployment on low-power edge devices.

Core Idea: Neural HMM with Amortized Inference. We propose replacing the fixed-parameter HMM with a **Neural HMM** where emission parameters are predicted by a recurrent neural network conditioned on a recent sensor context window:

$$\mu_k^{(t)}, \Sigma_k^{(t)} = f_\phi(X_{t-W:t}) \tag{52}$$

The neural network f_ϕ learns to adapt emission parameters dynamically based on recent sensor history, capturing drift without requiring hand-tuned recalibration. This is a neural-symbolic hybrid: the symbolic HMM structure (Markov chain, latent health states) provides interpretability and structural guarantees, while the neural component provides adaptability.

Amortized Inference. An inference network $q_\psi(Z_{1:T} \mid X_{1:T})$ is trained to approximate the posterior directly (variational auto-encoder style), enabling **real-time inference** at $O(1)$ per observation without running Forward–Backward:

$$q_\psi(Z_{1:T} \mid X_{1:T}) \approx p(Z_{1:T} \mid X_{1:T}, \theta) \tag{53}$$

The recognition network q_ψ is trained by maximizing the ELBO end-to-end, with f_ϕ and q_ψ jointly optimized.

6.2.2 Research Proposal: One Page

Title: Amortized Bayesian Inference for Non-Stationary Machine Health Monitoring in Sub-Saharan African Industrial Environments

Refined Inferential Question. Given non-stationary sensor streams in a resource-constrained SSA industrial environment, can an amortized neural-symbolic inference engine maintain calibrated posterior estimates of machine health states Z_t in real time, while adapting to sensor drift without offline recalibration?

Research Gap. Existing predictive maintenance systems either (a) assume stationarity (breaking in SSA environments with sensor drift) or (b) require continuous cloud connectivity and expert recalibration (infeasible in SSA). No existing work combines adaptive emission modeling with amortized real-time inference for low-resource edge deployment.

Proposed Methodology.

1. *Data:* Simulate realistic sensor drift using non-stationary DGPs with time-varying $\mu_k^{(t)}$ (linear drift + periodic fluctuation). Collaborate with SSA manufacturing partners for real sensor validation data.
2. *Model:* Neural HMM with LSTM-parameterized emissions f_ϕ + amortized recognition network q_ψ (bidirectional GRU encoder).
3. *Training:* ELBO maximization:

$$\mathcal{L}(\phi, \psi) = \mathbb{E}_{q_\psi}[\log p(X \mid Z, f_\phi(X))] - D_{\mathrm{KL}}(q_\psi(Z \mid X) \| p(Z)) \tag{54}$$

4. *Inference:* Single forward pass through q_ψ for real-time posterior approximation at $O(1)$ per observation.

Evaluation Plan.

Metric	Static HMM	Neural HMM
KL divergence from true posterior	Measured	$\leq$ Baseline
Accuracy under sensor drift	Degrades over time	Maintained
Inference latency	$O(T \cdot K^2)$	$O(1)$ per observation
Recalibration requirement	Offline retraining	None (adaptive)

Anticipated Contributions. (1) First amortized inference framework for HMMs in non-stationary SSA industrial contexts. (2) Demonstrated real-time edge deployment at $O(1)$ inference cost. (3) Open-source implementation and real SSA sensor dataset release.

SSA Impact. Adaptive real-time inference with no recalibration is particularly valuable in SSA contexts where maintenance engineers may lack data science expertise and where sensor replacement is costly. This system would democratize predictive maintenance for low-resource industrial environments.

6.3 Decision Support System: Complete Pipeline Demonstration

To demonstrate the operational value of the inference pipeline, we implement a maintenance decision support system with calibratable threshold τ:

$$\text{Alert}(t) = \mathbf{1}\left[p(Z_t = \text{Critical} \mid X_{1:T}) > \tau\right] \tag{55}$$

Decision Support System (τ

```
Total maintenance alerts triggered:    43
True Critical time steps in data:      39
Confusion Matrix:
  TP=37, FP=6, FN=2, TN=155
  Precision: 0.861
  Recall:    0.949
  F1-score:  0.903
```

Interpretation. The system achieves 94.9% recall—it detects nearly all true Critical states. The 85.2% precision means 14.8% of alerts are false positives (unnecessary maintenance checks). In the SSA cost model, a false positive (unnecessary inspection) costs far less than a false negative (missed failure), making high-recall operation appropriate. The threshold τ provides a direct mechanism to trade precision against recall according to the relative cost structure of the specific industrial context.

6.4 Complete Pipeline Summary

Complete Project Summary

Component	Result
Dataset	Kaggle Machine Predictive Maintenance (10,000 rows)
Synthetic DGP	$T = 200$, $K = 3$ states, $D = 3$ sensors
Milestone I	HMM model, Dirichlet-NW priors, DGP calibrated from real data
Milestone II	Forward-Backward: 95.0% accuracy, 0.030s runtime
Milestone III	Gibbs MCMC: $\hat{R}_{\max} = 1.019$, $D_{\mathrm{KL}} = 0.00018$ bits, $O(K)$ scaling
Milestone IV	Baum-Welch EM converged (iter 23), BIC selects $K = 3$, diagnostics clean
Milestone V	Neural HMM proposal, F1=0.903 decision system
Mutual Information	$I(Z_t; X_{1:T}) \approx 0.917$ nats
Posterior entropy	Mean $H = 0.182$ nats (16.6% of max)
SSA Relevance	Addresses \$38,500/hr downtime; targets $\leq 30\%$ maintenance cost reduction

7 Summary of All Key Mathematical Formulas

$$\hat{\theta} = \arg\max_{\theta} P(X \mid \theta) \tag{56}$$

MLE: finds the parameter values that best explain the observed sensor data.

$$P(Z, \theta \mid X) = \frac{P(X \mid Z, \theta)\, P(Z \mid \theta)\, P(\theta)}{P(X)} \tag{57}$$

Bayesian posterior: combines prior knowledge about machine degradation with observed sensor data.

$$p(Z_t = i \mid X_{1:T}) = \frac{\alpha_t(i)\, \beta_t(i)}{\sum_{k=1}^{K} \alpha_t(k)\, \beta_t(k)} \tag{58}$$

Forward–Backward posterior: exact per-step posterior.

$$\hat{A}_{ij} = \frac{\sum_{t=1}^{T-1} \xi_t(i,j)}{\sum_{t=1}^{T-1} \gamma_t(i)}, \qquad \hat{\mu}_k = \frac{\sum_t \gamma_t(k) X_t}{\sum_t \gamma_t(k)} \tag{59}$$

Baum-Welch M-step: closed-form parameter updates from expected sufficient statistics.

$$p(Z_t \mid Z_{-t},\, X_{1:T}) \propto p(Z_t \mid Z_{t-1})\, p(Z_{t+1} \mid Z_t)\, p(X_t \mid Z_t) \tag{60}$$

Gibbs sampling local conditional: used in approximate MCMC inference.

$$\hat{R} = \sqrt{\frac{\hat{V}}{W}}, \qquad \hat{V} = \frac{N-1}{N} W + \frac{1}{N} B \tag{61}$$

Gelman-Rubin statistic: convergence diagnostic ($\hat{R} < 1.05$ = converged).

$$D_{\mathrm{KL}}(P_{\mathrm{exact}} \,\|\, Q_{\mathrm{appx}}) = \sum_{t,k} \gamma_{\mathrm{exact}}^{(t,k)} \log\left(\frac{\gamma_{\mathrm{exact}}^{(t,k)}}{\gamma_{\mathrm{appx}}^{(t,k)}}\right) \approx 0.00018 \text{ bits} \tag{62}$$

KL divergence between exact and approximate posteriors: negligible approximation error.

$$H(Z_t \mid X_{1:T}) = -\sum_{k} p(Z_t = k \mid X) \log p(Z_t = k \mid X) \tag{63}$$

Posterior entropy: measures residual uncertainty after observing all sensor data.

$$I(Z_t; X_{1:T}) = H(Z_t) - H(Z_t \mid X_{1:T}) \approx 0.917 \text{ nats} \tag{64}$$

Mutual information: quantifies the diagnostic value of the sensor system.

$$\mathrm{BIC}(M) = -2 \log p(X \mid \hat{\theta}_M) + |\theta_M| \cdot \log T \tag{65}$$

Bayesian Information Criterion: model selection via penalized likelihood.

Appendix: AI Use Statement

AI Use Statement for CSC5341 Project

Tools Used. The following AI tools were used in a limited and carefully controlled capacity during the implementation phase of this project: Claude (Anthropic) for occasional code scaffolding and conceptual clarification of specific algorithmic steps.

Specific and Concrete Uses.

AI assistance was restricted exclusively to the following narrow implementation tasks:

1. *Code scaffolding for numerical stability.* When implementing the Forward–Backward algorithm, I encountered numerical underflow issues in the forward pass over long sequences. After deriving the scaling normalization procedure analytically from the Bishop (2006) derivation, I used the prompt: *"Given this normalized forward recursion $\tilde{\alpha}_t(j) = \alpha_t(j)/\sum_i \alpha_t(i)$, generate Python code that accumulates scaling constants to recover the correct log-likelihood."* I then verified the generated code against my manual derivation, correcting a subtle indexing error where the log-sum of scaling constants was accumulated in the wrong order.

2. *Visualization syntax.* For generating multi-panel diagnostic figures (trace plots, R-hat bar charts), I used the prompt: *"Generate a matplotlib figure with 2 subplots: top panel is a time-series plot with fill_between for state regions, bottom panel is a bar chart colored by threshold."* All axis labels, titles, and interpretive content were written independently.

3. *Debugging the xi computation in Baum-Welch.* After deriving the $\xi_t(i,j)$ formula analytically, I used AI to check for a broadcasting error in a 3-dimensional NumPy operation, using the prompt: *"Here is my ξ computation using alpha[t,i], A[i,j], B[t+1,j], beta[t+1,j]; identify any broadcasting issues in this NumPy code."* The AI identified a missing axis in the normalization; I verified this correction against the expected sum-to-one property $\sum_{i,j} \xi_t(i,j) = 1$.

Critical Validation Process.

AI outputs were never trusted without independent mathematical verification. My validation process was systematic:

For all inference algorithms (Forward–Backward, Viterbi, Gibbs Sampler), I first derived the mathematical update equations from first principles—working through the conditional probability manipulations by hand before writing any code. This derivation-first approach meant that any AI-generated code was checked against a mathematical specification I already possessed.

Specifically: the Baum-Welch M-step updates were derived by computing $\partial Q/\partial \mu_k = 0$ and $\partial Q/\partial \Sigma_k = 0$ using matrix calculus before any code was written. The resulting closed-form updates were then used as the ground truth against which AI-scaffolded code was evaluated. The Gelman-Rubin $\hat{R}$ implementation was verified by checking that $\hat{R} = 1$ exactly when all chains are initialized identically (a known analytical property).

Intellectual Ownership.

The following components were exclusively my own intellectual work, with no AI input:

- The formulation of predictive maintenance as an HMM inference problem and the selection of $K = 3$ health states with Gaussian emissions
- The justification for the Bayesian paradigm over the frequentist alternative, including the decision-theoretic argument based on expected cost minimization
- The selection of MCMC over Mean-Field VI based on the information-theoretic argument that the Mean-Field factorization would create an irreducible KL gap by severing Markov chain dependencies
- The design of the Vectorized Even-Odd Block Gibbs Sampler, including the conditional independence argument that justifies simultaneous block updates
- All interpretation of inference results, diagnostic metrics, and uncertainty quantification
- The critical synthesis connecting paradigm choice to algorithm selection, information theory, and SSA deployment implications
- The Neural HMM research proposal, including the amortized inference formulation and the ELBO training objective

Reflection.

AI tools modestly accelerated certain implementation tasks—primarily by reducing time spent on Python syntax issues and NumPy broadcasting mechanics. However, this project fundamentally required independent statistical reasoning that no AI tool substituted for. The most difficult and consequential decisions—why Bayesian inference is appropriate here, why MCMC preserves temporal dependencies that VI destroys, how to interpret the posterior entropy as a diagnostic, and what the Baum-Welch convergence rate implies about the dataset—required careful engagement with statistical theory that I developed through the course. AI assistance was a controlled syntactic tool, not a conceptual one.
